Examination of land at Louden Street, South Hobart

by B. D. Weldon

Abstract

Steep land in Louden Street, South Hobart is underlain by Triassic age siltstone and sandstone sediments and Jurassic age dolerite. The bedrock occurs at variable depth and is overlain by clayey soils which are sandy or gravelly in places. Development of the land for domestic purposes is considered possible provided all structures have footings keyed into competent bedrock, and all excavations and fills are properly designed, engineered and constructed.

INTRODUCTION

The owner of land in Louden Street, South Hobart requested an assessment of the property with regard to potential housing development. The property encompasses four building allotments. The land is steep and has been largely cleared of natural vegetation. A series of test pits were recommended to assess subsurface conditions.

GEOLOGY

Jurassic age dolerite crops out in road cuttings on the upslope side of Louden Street opposite the property under consideration. Triassic age siltstone and sandstone crops out in road cuttings towards the end of Louden Street; and Triassic age sandstone crops out in cliffs between Syme and Tara Streets southeast of the property under consideration. The soils exposed near Louden Street are doleritic but show traces of sand.

TEST PITS

Six test pits were excavated by a Kubota KH-151 tracked mini-excavator at the approximate locations shown schematically in Figure 1. The engineering logs are presented in Appendix 1.

The test pits indicate that bedrock was encountered at 1.5, 1.1, 1.9, 2.0, 2.0, and 0.9 m depth in test pits 1 to 6 respectively. The bedrock is variably weathered from highly – extremely weathered in test pit 6, where it has soil-like properties; to slightly-moderately weathered in test pit 1, where it is competent rock. The bedding in the Triassic age sediments is variable but usually with a shallow dip component out of the slope.

The weathered bedrock is overlain by firm to hard clayey soil layers, some with sand and gravel. Near Louden Street, these soil layers are derived largely from the weathering of dolerite. Further downslope, the soil usually consists of an upper layer derived from the weathering and erosion of dolerite, underlain by soil layers derived from the weathering of siltstone and sandstone. An intrusion of dolerite occurs between 2.0 and 2.4 m depth in test pit 5. A firm to stiff, silty clay layer occurs between 0.7 and 0.8 m depth in this pit. This layer contains lumps of charcoal. It appears to be the original topsoil which has been buried by fill, perhaps at the time of constructing Louden Street.

ASSESSMENT

The property is covered by predominantly clayey soils which vary considerably in thickness. Some sandy and gravelly soils are present. In places these have the potential to act as aquifers (i.e. a conduit for groundwater) which could soften the clayey soil layers and lead to a reduction in their strength. For this reason, cautious development of the site is advocated.

Any permanent excavation should be retained by a properly designed, engineered and constructed retaining wall which is properly drained. Areas where permanent filling is to be placed should be properly prepared by removing the topsoil and placing the filling in layers onto benches cut along the slope. The fill should be placed in layers which are properly compacted to achieve maximum density. If wet or poorly drained areas are encountered where fill is to be placed, the materials in these areas should be removed, drains provided and more competent fill materials imported if necessary.

As previously mentioned, the bedrock has a dip component out of the slope and for this reason all structures on the property should have their foundations keyed into competent bedrock rather than resting on the surface of the bedrock.

Pole-frame style housing, with poles keyed into the bedrock, appears to be most appropriate for this steep property.

CONCLUSIONS

This rather steep property is underlain by sandstone and dolerite bedrock. The depth to bedrock varies considerably, with the bedrock occurring between 0.9 and 2.0 m depth in the test pits excavated. The weathering state of the bedrock exposed by the test pits also varied considerably from

extremely weathered, soil-like materials to slightly weathered, jointed and bedded, competent rock.

The materials overlying the bedrock are generally considered to have sufficient bearing capacity for domestic buildings. However the steep slope, the presence of materials which are potential aquifers, combined with the presence of clayey materials which could be softened by the addition of water, and the component of dip in the bedrock out of the slope, all necessitate a cautious approach to development of the property. All structures should have footings keyed into the bedrock. All excavations should be retained by a properly designed, engineered, constructed and drained retaining wall. All fillings should be placed on

properly prepared ground and properly compacted. Under-drainage of fills may be necessary.

Provided the precautions mentioned above are strictly adhered to, development of the property in the vicinity of the area investigated by test pitting should not result in a change to the present stability of the slope. The property is large, covering four building allotments, and obviously if during development, either in the vicinity of the test pits or elsewhere on the property, subsurface conditions vary considerably from those derived from this assessment, a re-examination will be necessary.
